Forklift Differential

Differential for Forklifts - A differential is a mechanical tool that could transmit rotation and torque via three shafts, often but not all the time employing gears. It normally functions in two ways; in cars, it provides two outputs and receives one input. The other way a differential functions is to put together two inputs to produce an output that is the average, difference or sum of the inputs. In wheeled vehicles, the differential allows each of the tires to be able to rotate at different speeds while providing equal torque to all of them.

The differential is intended to drive a set of wheels with equal torque while enabling them to rotate at different speeds. While driving around corners, a car's wheels rotate at various speeds. Certain vehicles like for instance karts function without a differential and utilize an axle as a substitute. When these vehicles are turning corners, both driving wheels are forced to rotate at the identical speed, typically on a common axle that is driven by a simple chain-drive mechanism. The inner wheel must travel a shorter distance than the outer wheel while cornering. Without a differential, the effect is the outer wheel dragging and or the inner wheel spinning. This puts strain on drive train, resulting in unpredictable handling, difficult driving and damage to the roads and tires.

The amount of traction necessary so as to move whatever car will depend upon the load at that moment. Other contributing factors include momentum, gradient of the road and drag. Amongst the less desirable side effects of a traditional differential is that it could reduce grip under less than perfect circumstances.

The torque provided to every wheel is a product of the drive axles, transmission and engine applying a twisting force against the resistance of the traction at that particular wheel. The drive train can typically provide as much torque as required unless the load is extremely high. The limiting element is normally the traction under every wheel. Traction can be defined as the amount of torque that can be generated between the road surface and the tire, before the wheel begins to slip. The car would be propelled in the planned direction if the torque applied to the drive wheels does not exceed the limit of traction. If the torque utilized to every wheel does go beyond the traction threshold then the wheels would spin continuously.
